The Association between APOE Genotype and Memory Dysfunction in Subjects with Mild Cognitive Impairment Is Related to Age and Alzheimer Pathology

Apolipoprotein E · Mild cognitive impairment · Alzheimer’s disease · Memory strategies

Abstract
Background: Memory problems are a main feature of mild cognitive impairment (MCI) and may be related to the apolipoprotein E (APOE) ε4 allele. We investigated whether the effect of the APOE genotype on memory in subjects with MCI was dependent on age and underlying Alzheimer disease (AD) pathology. Methods: Subjects with MCI (n = 180) were selected from a memory clinic setting. Subjects with at least one APOE ε4 allele (n = 83) were compared to non-carriers on several memory measures. Subjects were reassessed 5–10 years later in order to identify those who developed AD. Results: In the middle-aged subgroup, the APOE ε4 allele was most strongly related to decreased subjective organization and in the old subgroup to a decreased delayed recall. After excluding subjects with incipient AD (n = 33), results remained similar in the middle-aged subgroup, but in the old subgroup the APOE genotype was no longer associated with memory dysfunction. Conclusion: The presence of the APOE ε4 allele is associated with impaired memory functioning in both middle-aged and old subjects with MCI, although the memory function affected varies with age. Its effect on memory function may be dependent on underlying AD pathology in elderly subjects, but not in middle-aged subjects.

Introduction
The apolipoprotein E (APOE) ε4 allele is a major risk factor for Alzheimer’s disease (AD) [1] and is associated with memory impairment both in subjects with AD and non-demented subjects [2–4]. The APOE ε4 allele may also affect memory function in subjects with mild cognitive impairment (MCI) [5–7]. MCI refers to cognitive impairment in subjects without dementia, and is associated with an increased risk for AD [8]. The relation between the APOE ε4 allele and memory function in MCI is still poorly understood. It is not clear whether the effect of APOE on memory function is mediated by underlying AD pathology [9], or is an independent effect of the APOE...
genotype [10]. In addition, in order to better understand the relation between APOE genotype and memory function it would be important to know whether the effect of APOE genotype is dependent on age, because underlying pathology in MCI may vary with age [2, 11]. In addition, it would be important to know which aspect of memory is most severely affected, because this may give an indication of which brain regions are involved. Previous studies in subjects with MCI, however, were conducted in elderly subjects only [6, 7], and mainly investigated learning and delayed recall.

The aims of the present study were to investigate the effect of the APOE e4 allele on memory function in middle-aged (40–59 years) and elderly (60–85 years) subjects with MCI from a memory clinic setting and to investigate whether the effect of APOE e4 allele on memory function was dependent on underlying AD pathology. To that end we followed subjects for 5–10 years and repeated analyses after exclusion of subjects who developed AD during this period. Besides learning and delayed recall, we also investigated memory measures that have not been investigated before such as primacy, recency, retention, intrusions, subjective organization, and serial clustering. Subjective organization and serial clustering are learning strategies that are used by a subject to learn new information. These strategies are impaired in early AD [12–14].

Methods

Subjects

Subjects were selected from an ongoing longitudinal study of non-demented subjects referred to the Maastricht Memory Clinic. The Memory Clinic is an outpatient clinic of the University Hospital Maastricht [15]. The design of the study has been described in detail elsewhere [8, 15]. Consecutive patients were included at the time of the first visit to the Memory Clinic. Inclusion criteria were age 40 years or older, and MCI, defined as a score of 2 or 3 on the Global Deterioration Scale (GDS) [16]. This broad definition of MCI is consistent with that of other studies [17–19]. It was used because subjects with AD in the predementia stage do often not meet more strict criteria of MCI, such as criteria for amnestic MCI [20–22]. Exclusion criteria were dementia at baseline and an apparent cause for their cognitive impairment, such as cerebrovascular disorders, brain trauma, endocrine disorders or psychiatric disorders other than mild affective disorders at baseline [23]. Subjects included in this study were referred to the Memory Clinic by general practitioners (76%), neurologists (6%), neurologists (12%) or others (6%).

For the present study we selected those subjects eligible for the 5- or 10-year follow-up (n = 453). During this period five versions of the Auditory Verbal Learning Test (AVLT) [24] were used at baseline. In order to avoid a version effect of the AVLT, we only included subjects with the version that was most commonly used (n = 367). Subjects with this version had similar age, sex, level of education, Mini Mental State Examination (MMSE) score [25], GDS score [16] and Blessed Dementia Rating Scale score (BDS) [26] as subjects with other versions of the AVLT. Next we excluded subjects on whom APOE genotyping had not been performed (n = 187). The final study sample consisted of 180 subjects. Data on APOE genotype was mainly unavailable because blood for genotyping was collected at follow-up during a specific time period. In addition, a few subjects refused APOE genotyping. Subjects whose APOE status was not available were significantly older (60.7 vs. 57.0 years, p = 0.001) compared to subjects whose APOE status was known. Both groups were comparable with respect to educational level, sex distribution, MMSE score, Hamilton Depression Rating Scale (HDRS) score [27] and total delayed recall at baseline, as well as percentage of subjects with AD at follow-up.

Clinical Assessment at Baseline and Follow-Up

At baseline, all subjects underwent a standardized assessment, which included a detailed history of the subject, a psychiatric, neurological, and physical examination, the MMSE [25], GDS [16], BDS [26], HDRS [27] and the appropriate laboratory tests, a neuropsychological assessment, and a CT or MRI as described elsewhere [15]. For descriptive purposes we subdivided subjects at baseline into five MCI groups based on the neuropsychological test performances in the domains of memory, attention, executive functioning, language, and visuoconstruction, as described elsewhere [8]. Performance in a cognitive domain was considered impaired if the score on at least one test from that domain was below –1.5 standard deviation (SD) of age-, sex- and education-corrected means of healthy control subjects [28–30] except for the measure of visuoconstruction in which impairment was based on a qualitative rating [8]. Subjects without impairment in any domain were classified as subjective complaints (n = 53); subjects with only impairments in one non-memory domain as non-amnestic MCI single domain (n = 33), subjects with only impairments in more than one non-memory domain as non-amnestic MCI multiple domain (n = 33), subjects with impairment in only the memory domain as amnestic MCI single domain (n = 13), and subjects with both impairments in memory and non-memory domains as amnestic MCI multiple domain (n = 47). One subject could not be classified, because non-memory tests had not been done. The criteria for non-amnestic MCI and amnestic MCI also require intact activities of daily living [31]. This was operationalized as the absence of dementia and a score below 4 on the GDS, which was part of the inclusion criteria of the study, in agreement with previous studies [20].

Two, 5 and 10 years after baseline, the subjects were invited for a follow-up assessment. This assessment included a standardized questionnaire about medical history and cognitive complaints, the MMSE, GDS, BDS, HDRS, and an extensive neuropsychological assessment comparable to the baseline assessment. Subjects who refused to come for the follow-up were assessed via a telephone interview, which included a standardized questionnaire about medical history and cognitive complaints, and the Telephone Interview for Cognitive Status [32]. The diagnosis of dementia and AD was made independently by both a neuropsychiatrist and a neuropsychologist according to the DSM-IV and NINCDS-ADRDA criteria [33, 34]. Both were blinded to the baseline results. If disagreement on the diagnosis occurred, a consen-
sus meeting was held. Subjects who were diagnosed as being demented at follow-up were not invited for the next follow-up.

**Outcome at Follow-Up**

The average follow-up duration was 8.7 years. Because blood for genotyping was collected at follow-up, all subjects had at least one follow-up. Of the 180 subjects included at baseline, 140 subjects had been in the study long enough to be contacted for the 10-year follow-up and cognitive outcome was available for 120 (86%) of them, the other subjects (n = 40) only had a 5-year follow-up. Reason for no outcome at the 10-year follow-up was because the subjects refused (n = 6), had died (n = 7), or were untraceable (n = 7). Subjects with and without cognitive outcome had comparable age, sex distribution, level of education and MMSE score. During the total follow-up period 33 subjects (18%) had developed AD. After 5 years 25 subjects had developed AD, and after 10 years 8. Of those with AD at follow-up, 6 were younger than 60 years (of whom 5 subjects were carriers of the APOE e4 allele) and 27 were older than 60 years (of whom 21 subjects were carriers of the APOE e4 allele). Fourteen subjects who developed AD had a baseline GDS score of 2, and 19 subjects had a baseline GDS score of 3.

**Measures of Memory Impairment**

In the Dutch version of the AVLT [24, 28], 15 unrelated monosyllabic words are presented 5 times in the same order and after each presentation the subject is asked to recall as many words as possible. After 20 min, in which non-verbal tests were performed, delayed recall was tested. The AVLT can be used to investigate the following aspects of verbal memory functioning:

- **Learning.** Total of correctly remembered words from the 5 immediate recall trials.
- **Delayed Recall.** Total number of correctly remembered words after 20 min.
- **Retention.** Total delayed recall score divided by the highest score at the 5 immediate recall trials, multiplied by 100.
- **Intrusion.** Number of recalled words in the 5 immediate recall trials that were not part of the AVLT.
- **Subjective Organization.** Subjective organization refers to the constancies in response ordering that develop in a series of free recall trials. Observed ITR is the number of pairs of items recalled on trial t and t + 1 in adjacent output positions in either of the two possible orders. For example, if after the first trial ‘flower’ and ‘car’ were mentioned after each other and in the second trial ‘flower’ was followed by ‘car’ or ‘car’ was followed by ‘flower’, this counted as one observed ITR. Expected ITR is the expected number of pairs of items, c is the number of common items recalled on both trials t and t + 1, h is the number of items recalled on trial t, and k is the number of items recalled on trial t + 1. An outcome of 0 indicates that the number of observed ITRs is equal to the number of expected ITRs. A score higher than 0 indicates more use of subjective organization than expected by chance.

**Serial Clustering.** Serial clustering is a measure for the reproduction of words in the same order as that they were presented. This form of clustering indicates a more passive approach to recall. Serial clustering was calculated by dividing the number of observed serial clusters by the number of serial clusters that could be expected to occur by chance [39, 40].

- **Primacy Effect.** Ratio of the number of words remembered from the first 3 words of the list divided by 3.
- **Recency Effect.** Ratio of the number of words remembered from the last 3 words of the list divided by 3.

**APOE Genotyping**

APOE genotype was determined on genomic DNA extracted form EDTA-anticoagulated blood using the polymerase chain reaction technique [41–43]. Genotyping was done blinded for all clinical data. Eighty-three subjects (46%) had one or two e4 alleles (APOE+), i.e. e4e4 (n = 8, 4%), e3e4 (n = 69, 38%), and e2e4 (n = 6, 3%). Ninety-seven subjects (54%) had no e4 allele (APOE−), i.e. e3e3 (n = 76, 42%), e2e3 (n = 20, 11%), and e2e2 (n = 1, 0.6%).

**Statistics**

Statistical analyses were performed using the Statistical Package for Social Sciences for the Macintosh, version 11. To analyse baseline differences between carriers and non-carriers of the APOE e4 allele independent t tests were used for continued variables, and χ2 tests for categorical variables. Level of education was classified into low (at most primary education), middle (junior vocational education), or high (senior vocational education or academic training) [44]. Univariate variance analyses (ANOVA) adjusted for age, education and sex were used to test group differences in memory performance between carriers and non-carriers of the APOE e4 allele. To adjust the ANOVA analyses for multiple comparisons we used an α-level of 0.01. Stepwise binary logistic regression analysis with correction for age, sex and education was used to identify the memory variable to which the APOE e4 allele was strongest related. All analyses were repeated without subjects who had developed AD within the study period of 10 years and were performed in the total group and in subjects aged 40–59 years (middle-aged subgroup) and 60–85 years (older subgroup).

**Results**

**Baseline Characteristics**

Baseline characteristics of carriers and non-carriers of the APOE e4 allele are presented in table 1. In the total group, APOE e4 carriers were about 4 years older, had a significantly lower MMSE and delayed recall score, a slightly higher GDS score, a lower HDRS score, and more often amnestic MCI (45 vs. 24%, p = 0.003) compared to non-carriers. Educational level and sex

Data are mean ± SD; p values are uncorrected for multiple testing.

APOE ε4– = Non-carriers of the APOE ε4 allele; APOE ε4+ = homozygote or heterozygote carriers of the APOE ε4 allele.

distribution were comparable. In the middle-aged subgroup, baseline characteristics and distribution of MCI subtypes was comparable between subjects with and without the APOE ε4 allele. In the elderly subgroup, APOE ε4 carriers had a lower score on the delayed recall test than subjects without the APOE ε4 allele. The APOE ε4 allele was more common in subjects older than 60 years (58%) than in the middle-aged subgroup (40%, p = 0.015).

Effect of APOE on Memory Function

Memory performances of carriers and non-carriers of the APOE ε4 allele are presented in table 2. In the total sample, carriers of the ε4 allele had lower scores on learn-
ing, delayed recall, and subjective organization. None of the memory measures showed a significant interaction between age and the APOE genotype. In subjects younger than 60 years, APOE e4 carriers had lower scores on learning and subjective organization, while in the elderly subgroup APOE e4 carriers had lower scores on learning and delayed recall (table 2). After correction for multiple comparisons learning did not reach statistical significance in the middle-aged and old subgroup.

Binary logistic regression analyses, adjusted for age, sex and education showed that in the total sample the APOE e4 allele was most strongly related to learning performance (p = 0.004). In middle-aged subjects, the APOE e4 allele was most strongly related to subjective organization (p = 0.011), while in the elderly subjects the APOE e4 allele was most strongly related to delayed recall performance (p = 0.02).

Effect of Underlying AD Pathology

When the subjects with AD at follow-up were excluded from the analyses (6 in the 60+ group, and 27 subjects in the 60+ group), the APOE e4 allele was associated with lower scores on learning in the total group (p = 0.025). In middle-aged subjects, the APOE e4 allele was still associated with lower scores on subjective organization (p = 0.028), but no longer with learning. In the 60+ group, the APOE genotype was no longer associated with any of the memory measures.

Discussion

In the present study, we found an effect of the APOE e4 allele on various aspects of memory in subjects with MCI, which depends on age and underlying AD pathology. In elderly subjects, the APOE e4 allele was most strongly related to delayed recall performance, compared to subjective organization in the middle-aged subgroup. The effect of APOE on memory function may have been related to underlying AD pathology in subjects over 60 years, but not in middle-aged subjects.

The effect of the APOE e4 genotype on delayed recall and learning in elderly subjects with MCI is in line with previous studies [5, 6]. It suggests involvement of the medial temporal lobe as this region plays an important role in these memory functions. Indeed, there is evidence that elderly subjects with MCI with an APOE e4 allele have more atrophy in this region compared to subjects without an APOE e4 allele [45]. The effect of the APOE e4 allele on memory functioning may have been modulated by the degree of underlying AD pathology, since after exclusion of subjects who developed AD, the APOE genotype was no longer associated with memory performance. This finding is consistent with a population-based study in elderly subjects which showed that the APOE is no longer associated with cognition after correction for amyloid load in the brain [9]. However, the lack of an effect of APOE genotype on memory after exclusion of incipient AD cases might also have resulted from a lack of statistical power, because after the exclusion of AD subjects only 10 subjects older than 60 years carried the APOE e4 allele. It should be noted that we assumed that AD pathology was present in subjects who progressed to clinical AD at follow-up, but we did not have imaging or cerebrospinal fluid markers to quantify AD pathology more directly. This may be particularly useful for the younger subjects as it may take longer for these subjects to develop clinical AD.

In subjects younger than 60 years, the e4 allele was most strongly associated with subjective organization, and to a lesser extent with learning. Subjective organization is an effortful learning strategy requiring an active reorganization of incoming information to enhance the quality of encoding, and is thought to be mediated by the prefrontal lobe [46–49]. In order to investigate whether this effect was mediated by impairment in executive function, we post hoc repeated the analyses with correction for Stroop card III score and Trial Making Test B score [50, 51]. In these analyses, subjective organization remains significantly related to APOE genotype, which suggests that subjective organization problems in APOE e4 carriers cannot be explained by impairments in executive functioning. No other studies have investigated the effect of APOE on memory in middle-aged subjects with MCI, but in healthy young and middle-aged subjects the APOE e4 allele did not have an effect on memory function [52]. The lack of effect in young and middle-aged healthy APOE e4 carriers could be explained by test selection, because only measures of learning or delayed recall were tested, which was not severely affected by the APOE e4 allele in our study. Alternatively, the effect of the APOE e4 allele on cognitive function in younger subjects may become apparent only if impairment is severe enough to meet criteria of MCI and leads to referral to a memory clinic.

The effect of the APOE e4 allele on memory functioning in the middle-aged subgroup seemed not to be modulated by incipient AD, because after exclusion of subjects who converted to AD subjective organization remained associated with the e4 allele. This could mean that the
APOE ε4 allele directly affects memory functioning independently of AD-related pathology, for example by its effect on lipid or glucose metabolism [10]. Another explanation is that the memory problems were related to the degree of AD pathology, but that in these middle-aged subjects the follow-up interval was not long enough to identify everyone who would progress to clinical AD. In that case, subjective organization could be a very early marker of AD [12–14]. This may be investigated using PET amyloid imaging or cerebrospinal fluid markers of AD pathology, which were not available in the present study.

There is ample evidence that the APOE ε4 allele affects brain functioning in parietal, temporal and prefrontal regions in young to middle-aged subjects who are cognitively intact [53–55]. The interpretation of these studies is still controversial. Some studies suggest that these brain abnormalities reflect early AD as AD pathology is found in the same regions and may be present decades before the onset of dementia [53, 56]. Others consider this unlikely and suggest that these abnormalities are a direct effect of the APOE genotype on lipid or glucose metabolism that may facilitate the onset of AD at a later age [57]. The effect of APOE on frontal lobe functioning in young to middle-aged subjects may explain the effect of APOE on subjective organization in the present study [53, 58–61]. Although neuroimaging studies in this age range showed also impairments in the medial temporal lobe, learning and delayed recall were not severely affected in the middle-aged subgroup in our study [57, 60, 62]. One explanation is that these memory functions could still be compensated for.

Serial clustering, primacy, recency, intrusions and retention were not related to APOE genotype. Serial clustering, primacy, and recency do not require active organization of the incoming information and are more related to working memory and short-term memory processes. In general, these aspects of memory functioning are relatively less sensitive to neurodegeneration [14]. The lack of an effect of the number of intrusions might be explained by the low prevalence of intrusions in the total sample. Retention was lower in APOE ε4 carriers, but did not reach statistical significance.

The APOE allele distribution in our sample is comparable with that reported in other studies with MCI [1, 7]. The prevalence of the APOE ε4 allele in our middle-aged subgroup (40%) and in the elderly subgroup (58%) was higher than the prevalence of the APOE ε4 allele in subjects from the general population aged 40–60 (32%) and 60–85 years (24%) from the Maastricht Aging Study [63]. This suggests that carriers of the APOE ε4 allele more often have memory problems leading to a referral to a memory clinic than non-carriers, even at a relatively young age.

We used a broad definition of MCI in accordance to previous studies [17–19]. As a result, we also included subjects with cognitive complaints in the absence of impairment on cognitive tests (n = 53), although some of them (n = 3) had mild functional impairment defined as a score of 3 on the GDS. If we excluded subjects with subjective complaints from the analyses, the effect of the APOE genotype on memory function remained similar in the total sample. In the age subgroups, however, APOE ε4 was no longer associated with learning and subjective organization in the middle-aged subgroup, and with the delayed recall score in the older subgroup. This is probably because we limited the range of memory impairment and reduced statistical power due to smaller sample size.

The strengths of the present study include the large sample size, the broad age range, the variety of memory measures tested, and the long follow-up period to identify subjects with incident AD. The study also had some limitations. Firstly, after exclusion of those who developed AD the sample size in the older subgroup was small, resulting in only 10 subjects older than 60 years who carried an ε4 allele. Secondly, because subjects were selected from a memory clinic results may not be generalizable to other settings and subjects with MCI according to other definitions. Thirdly, the follow-up period may be too short to identify all subjects who convert to AD. Another point is that blood samples for APOE genotyping were collected at follow-up only. However, the baseline characteristics of the subjects with data on APOE genotype and those without data on APOE genotype were comparable, except regarding age, which was 3 years lower in those with genotyping. This suggests that genotyping at follow-up may not have introduced a strong bias. Finally, we used an indirect measure of AD pathology rather than a direct measure such as PET amyloid imaging or cerebrospinal fluid markers as discussed above.

In conclusion, the findings of this study, that investigated several aspects of verbal memory across a broad age range in clinical subjects with MCI, showed that APOE genotype has an effect on memory that is dependent on age. In subjects aged 60 years and older, memory functions associated with the medial temporal lobe were predominantly affected, while in middle-aged subjects memory functioning related to the frontal lobe was most strongly affected. Together with the observation that
memory functioning was dependent on the degree of AD pathology in elderly subjects, but not in middle-aged subjects, this suggests that different mechanisms underlie the APOE-related memory dysfunction in different age groups. Whether the effect of APOE genotype on subjective organization in middle-aged subjects is indeed an AD-independent process needs to be investigated in future imaging studies and longitudinal studies with a longer follow-up.

Acknowledgements

The authors thank Nico Rozendaal for his help in data management and for computerization of the formulas for serial clustering and subjective organization. The study was supported by the ‘Hersenstichting Nederland’ (Dutch Brain Foundation), and in part by the Fund for Scientific Research Flanders (FWO-V), the Stichting voor Alzheimer Onderzoek (SAO), the Interuniversity Attraction Poles (IAP) program P5/10 and P6/43 of the Belgian Federal Science Policy Office (BELSPO), and the Special Research Fund (BOF) of the University of Antwerp. K.S. holds a postdoctoral fellowship of the FWO-F.
